The altitude from which transient 630-nm ("red line") light is emitted in transient dayside auroral breakup events is discussed. Theoretically, the emissions should normally originate from approximately 250 to 550 km. Because the luminosity in dayside breakup events moves in a way that is consistent with newly opened field lines, they have been interpreted as the ionospheric signatures of transient reconnection at the dayside magnetopause. For this model the importance of these events for convection can be assessed from the rate of change of their area. The area derived from analysis of images from an all-sky camera and meridian scans from a photometer, however, depends on the square of the assumed emission altitude. From field line mapping, it is shown for both a westward and an eastward moving event, that the main 557.7-nm emission comes from the edge of the 630 nm transient, where a flux transfer event model would place the upward field-aligned current (on the poleward and equatorward edge, respectively). The observing geometry for the two cases presented is such that this is true, irrespective of the 630-nm emission altitude. From comparisons with the European incoherent scatter radar data for the westward (interplanetary magnetic field $B_y > 0$) event on January 12, 1988, the 630-nm emission appears to emanate from an altitude of 250 km, and to be accompanied by some 557.7-nm "green-line" emission. However, for a large, eastward moving event observed on January 9, 1989, there is evidence that the emission altitude is considerably greater and, in this case, the only 557.7-nm emission is that on the equatorward edge of the event, consistent with a higher altitude 630-nm excitation source. Assuming an emission altitude of 250 km for this event yields a reconnection voltage of >50 kV during the reconnection burst but a contribution to the convection voltage of >15 kV. However, from the motion of the event we infer that the luminosity peaks at an altitude in the range of 400 and 500 km, and for the top of this range the reconnection and average convection voltages would be increased to >200 kV and >60 kV, respectively. (These are all minimum estimates because the event extends in longitude beyond the field-of-view of the camera). Hence the higher-emission altitude has a highly significant implication, namely that the reconnection bursts which cause the dayside breakup events could explain most of the voltage placed across the magnetosphere and polar cap by the solar wind flow. Analysis of the plasma density and temperatures during the event on January 9, 1989, predicts the required thermal excitation of significant 630-nm intensities at altitudes of 400–500 km.

1. INTRODUCTION

Much recent interest has been focused on transient auroral phenomena seen throughout the dayside, termed "dayside auroral breakup" events [Sandholt *et al.*, 1985, 1989a, b, 1990a, b, 1992a, b, Sandholt, 1988]. Such events can be observed at winter solstice from the Svalbard islands using all-sky cameras and meridian-scanning photometers. Combination of such measurements with data from the European incoherent scatter (EISCAT) radar has shown that they are associated with transient bursts of plasma flow and electron and ion heating [Lockwood *et al.*, 1989a, b, 1990a, b, c].

Lockwood *et al.* [1989a, b] have pointed out that the pattern of motion of these events is one of zonal motion around the polar cap boundary, followed by poleward motion into the polar cap, and that this is consistent with the expected behavior of newly opened field lines for a nonzero interplanetary magnetic field (IMF) B_y component. This is because the initially dominant action of magnetic tension decays and magnetosheath flow becomes more important as the newly opened flux tube evolves. Furthermore, events observed from Svalbard move eastward when the IMF B_y is negative but westward when it is positive [Sandholt, 1988; Sandholt *et al.*, 1992a]. This behavior is nearly always explained in terms of the magnetic tension on newly reconnected field lines. The only other explanation suggested to date postulates a B_y -dependent shift in the MLT of the location where a solar wind dynamic pressure pulse impacts upon the magnetosphere [Sibeck, 1990]. However, analysis of large traveling convection vortices, thought to be caused by solar wind dynamic pressure changes, shows them to always originate from near magnetic noon, independent of the sense of B_y [Sibeck, 1993]. In addition, the pressure

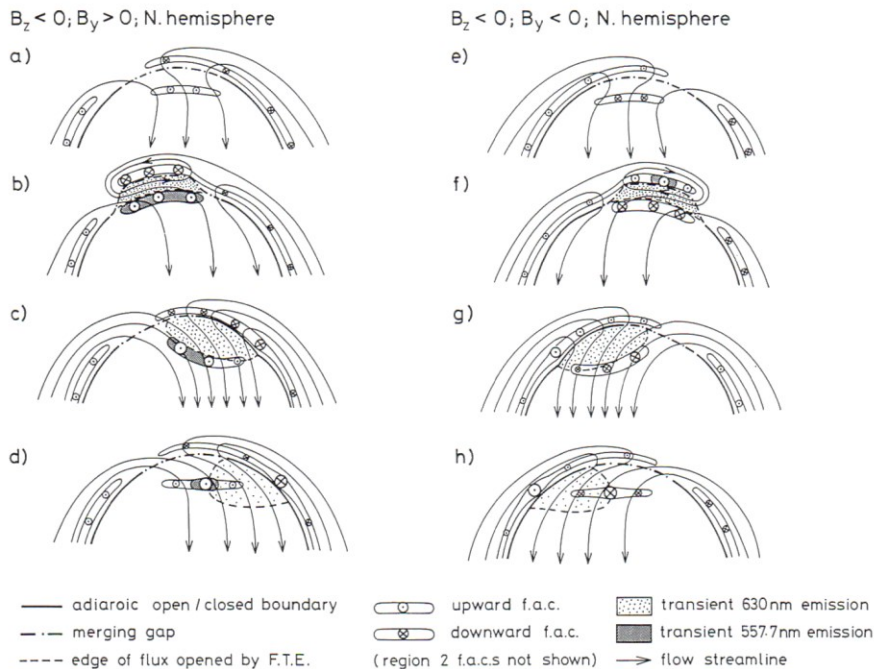

Fig. 1. Schematic of the motion of dayside breakup events, showing a sequence of snapshots, roughly 3 min apart, of the locations of field-aligned currents and 630 nm and 557.7 nm auroral transients for (a) IMF $B_y > 0$ and (b) $B_y < 0$ in the Northern hemisphere (adapted from Smith and Lockwood, 1990). Also shown are the corresponding plasma flows (adapted from Cowley *et al.* [1991]). For clarity, the region 2 field-aligned currents have been omitted.

pulse model predicts the phase motion of a vortical plasma flow pattern away from the point of impact, rather than a bulk plasma flow, as observed during dayside breakup events [e.g., Sandholt *et al.*, 1990a, b].

Other evidence that dayside breakup events are ionospheric signatures of transient reconnection bursts comes from the similarities to the behavior of magnetopause flux transfer events (FTEs), which are thought to be the magnetopause signatures of such bursts [Russell and Elphic, 1978, 1979; Haerendel *et al.*, 1978; Paschmann *et al.*, 1982; Berchem and Russell, 1984; Rijnbeek *et al.*, 1984; Farrugia *et al.*, 1987a, b, 1988; Lockwood, 1991]. The FTE events occur almost exclusively when the IMF is southward [Berchem and Russell, 1984], when they repeat quasi-periodically with a range of repetition periods between about 2 and 20 min [Elphic, 1988; Lockwood and Wild, 1993], with a mean value of about 8 min [Rijnbeek *et al.*, 1984]. This behavior is very similar to that found for the dayside breakup events [Lockwood *et al.*, 1989b]. Furthermore, Elphic *et al.* [1990] have shown that in the only example of the required simultaneous magnetopause and ionospheric observations, dayside breakup events did follow magnetopause FTEs with the expected delay [see Sandholt *et al.*, 1992b].

1.1. FTE Signatures and the Pulsating Cusp Concept

On the basis of these observations, Smith and Lockwood [1990] have proposed that the transient auroral event seen in the 630-nm oxygen red-line emissions is caused by cusp electron precipitation down the newly opened field lines. In this case, the variations in reconnection rate produced a pulsed cusp. The transient 557.7-nm oxygen green emission is, in their model, identified with the region of the transient,

filamentary upward field-aligned current associated with the motion of the newly opened flux. Figure 1a–1d adapted from Smith and Lockwood, shows the evolution of a northern hemisphere transient event for IMF $B_y > 0$. While the event moves westward under the magnetic tension, the upward field-aligned current (of the oppositely directed pair of currents required to transfer the momentum to the ionosphere) is situated on the poleward edge of the red-line transient. Sandholt *et al.* [1990b] have shown that the 557.7-nm arc fragments are colocated with the inferred position of this field-aligned current, for such an event. Figures 1e–1h show the corresponding sequence, for a northern hemisphere event with IMF $B_y < 0$. In this case the event moves initially eastward under magnetic tension, requiring the upward field-aligned current to be on the equatorward edge of the patch of newly opened field lines. Because this current is again associated with the 557.7-nm emission, the green-line auroral transient appears at the equatorward edge of the red-line event in this case. (Note that in the southern hemisphere, Figures 1a–1d would be expected to apply for IMF $B_y < 0$ and Figures 1e–1h for $B_y > 0$).

Figure 1 also shows schematically the variations in the plasma flows expected during these events. These flows are predicted using the concept of flow excitation developed by Cowley and Lockwood [1992] from high time resolution observations of the response of dayside convection to IMF changes. This model is based on the idea that convection is excited following a burst of reconnection only while the magnetosphere-ionosphere system tends toward its equilibrium configuration for the new amount of open flux. The time scale for this, and hence also of the decay of the enhanced flow, is found by both experiment and theory to be about

10–15 min. Cowley *et al.* [1991] and Smith *et al.* [1992] have used this model to predict the ionospheric signatures of FTEs and the corresponding morphology of cusp ion precipitation (the “pulsating cusp” model).

In order to explain the behavior of the associated plasma flows, here we discuss only the IMF $B_y > 0$, northern hemisphere case shown in Figures 1a–1d. Corresponding arguments can be applied to the case shown in Figures 1e–1h. Figure 1 shows the effect of a single square wave pulse of the dayside reconnection voltage. This pulse is superposed on a background reconnection voltage of 3Δ , where Δ is the separation of the flow equipotentials shown in Figure 1. The pulse is considered to last $\Delta t = 2$ min, during which the reconnection voltage rises to 9Δ . The sequence shown is considered to cover 12 min, over which period the average reconnection voltage is therefore 4Δ .

Figure 1 shows both of the two possible classifications of the open/closed field line boundary in the ionosphere. The first is a merging gap (shown as a dot-dashed line), at which closed flux is converted into open flux. By definition, therefore, this is the ionospheric projection of the reconnection X line, along which the reconnection voltage is applied. At all other points, the boundary is “adiarctic” (this term, meaning “not flowing across,” was introduced by Siscoe and Huang [1985]), as shown by the continuous solid line. The convection streamlines cross an adiarctic boundary which is moving in the Earth’s frame (although the flux tubes do not); only if the boundary is stationary in the Earth’s frame do the streamlines only cross the boundary at the merging gap [Lockwood and Cowley, 1992]. The latter is the case in Figure 1a, which shows some background, steady state flows driven by the background reconnection voltage 3Δ before the pulse of increased voltage. Figure 1b shows the situation 3 min later, during the burst of enhanced reconnection. At this time the voltage along both the magnetopause X line and the ionospheric merging gap, in their own rest frames, is 9Δ . However, Figure 1b the voltage along the merging gap in the Earth’s frame remains at 3Δ because the merging gap is moving equatorward in response to the enhanced reconnection. The only increased flows at this time arise because of the magnetic tension force on the newly opened flux. Because this case is for a positive IMF B_y and the northern hemisphere, the tension force results in the FTE signature (and the plasma within it) moving westward around the polar cap boundary.

After a further 3 min, the reconnection pulse is over, but the flows are enhanced, as shown in Figure 1c. The voltage associated with the flow streamlines which cross the dayside open/closed boundary is now 6Δ (twice that in Figure 1a). Half of this is associated with the ongoing reconnection at the background voltage of 3Δ . The other half is associated with the poleward return of the open/closed boundary which commences as soon as the enhanced reconnection pulse ends. Note that the flow streamlines cross the poleward moving adiarctic polar cap boundary to the west of the merging gap. Hence at this time the region of flow entry into the polar cap is considerably broader than the merging gap in its local time extent. The process is almost complete after a further 3 min Figure 1d, for which the boundary has almost returned to its equilibrium position and is moving more slowly poleward. The flow voltage is 4Δ . Three minutes later, the system will have effectively returned to the background, steady state shown in Figure 1a.

Averaged over the whole period of 12 min, the flow voltage is 4Δ . This is the same as the average reconnection voltage for the same period. However, at any one instant of time, the flow and reconnection voltages are not equal because of the latitudinal motion of the merging gap.

In this model, the application of a pulse of reconnection voltage causes the merging gap to move equatorward without necessarily causing any flow. To quantify the likely merging gap motion, consider a large reconnection pulse of 225 kV, lasting 2 min (over the 12 min considered here, such a pulse would contribute 37.5 kV to convection). Such a pulse would reconnect a total of 2.7×10^7 Wb, which for a merging gap length of 1500 km (and in the absence of any enhanced plasma flow), would require the merging gap to migrate equatorward by 360 km (that is, about 3° of latitude). In practice, the merging gap may not move quite so far, in which case some poleward flow will be excited at this time. For example, were the merging gap to move only 300 km, an average poleward flow of $(360 - 300)/(2 \times 60) = 0.5 \text{ km s}^{-1}$ would be driven during the reconnection pulse. After the reconnection pulse, poleward flow is excited as the merging gap returns poleward to its equilibrium location. If this proceeds at a constant speed for 10 min, as discussed above, this yields a poleward speed of the now inactive merging gap (that is, it is now adiarctic) of $300/(10 \times 60) = 0.5 \text{ km s}^{-1}$, which would also be the poleward plasma flow speed. Hence this example would give sawtooth oscillations in the latitude of the merging gap (of amplitude 3°), but a constant poleward flow of 0.5 km s^{-1} . Such motions of the merging gap were invoked by Lockwood and Smith [1989] to explain a cusp intersection by the DE 2 satellite as an ionospheric signature of an FTE. Indeed, Lockwood and Smith [1992] have recently used cusp spectrograms to show that the reconnection proceeded as a series of pulses of exactly the kind invoked above.

This simplistic case has been discussed here to illustrate the idea that pulsed reconnection does not necessarily give pulsed flow in the dayside ionosphere. The oscillatory merging gap latitude could result in constant dayside convection if the IMF B_y were small in magnitude. In practice, some variations in the flow (with the same period as the reconnection pulses) are likely to be present but may be small enough to evade detection. If the IMF B_y component is large in magnitude, east/west flow pulses would be expected, as a result of the magnetic tension on the newly opened flux. The observed cases of strong flow bursts, in conjunction with dayside breakup auroral transients, do show eastward or westward flow and are for strongly negative or positive IMF B_y , respectively [e.g., Lockwood *et al.*, 1989b].

Figure 1 and the above discussion consider one isolated pulse of reconnection followed by sufficient time for equilibrium to be largely reestablished. Observations of magnetopause FTEs indicate that reconnection pulses tend to recur with a mean interval of $\Delta\tau = 8$ min, when the IMF is southward. Lockwood and Wild [1993] have presented the distribution of inter-FTE periods, showing that in the majority (>80%) of cases, an event will recur within 10 min of the preceding one. This period is considered significant here because it is roughly the minimum time scale on which the magnetosphere-ionosphere system returns to an equilibrium state following a pulse of reconnection. (In addition, it is roughly the time following reconnection for which “cusp” magnetosheath plasma will precipitate to low altitudes down

a newly opened field line). Hence in general, a second reconnection event will perturb the system before the flow excited by the previous event has fully subsided, (and the cusp precipitation within the event has turned into the lower flux, lower-energy "mantle" precipitation). Hence more than one "active" event is likely to exist at any one instant. Figure 1 studies the more unusual case of an isolated reconnection pulse, only in order that the behavior of the system be more clearly demonstrated.

Hence in general, we would expect a second reconnection pulse before the merging gap has had time to retreat to its equilibrium location following the proceeding one. Hence the merging gap will show an equatorward trend consisting of rapid equatorward motions during the reconnection pulses and only partial, slower poleward returns during the interpulse intervals. This dayside erosion would continue throughout a substorm growth phase. Averaged over one growth phase, M. Lockwood (Transpolar voltage, convection, and the substorm cycle, submitted to the *Journal of Geophysical Research*, 1993) has found that the dayside flow voltage was equal to roughly half the reconnection voltage, the other half resulting in the equatorward motion of the merging gap [see Lockwood and Cowley, 1992]. This equatorward motion is interrupted by the onset of significant reconnection in the magnetotail after onset of the substorm expansion phase.

1.2. Evaluation of the Importance of Transient Events to Convection

Lockwood et al. [1990b] have pointed out that, with the above interpretation, the importance of these events to magnetospheric and ionospheric convection depends upon how much flux is reconnected by each burst. Because the ionosphere can, to a good order of approximation, here be considered to be incompressible (that is, the ionospheric field strength, B_i , is constant), the amount of newly reconnected flux ΔF can be estimated from the area of the event A to be $(A \times B_i)$. If the event forms in a time Δt (the duration of the burst of reconnection), the mean reconnection voltage in the burst is $(\Delta F/\Delta t)$. However, if the events repeat periodically with a period $\Delta \tau$, the amount of flux reconnected by the burst in each cycle of this length is still only ΔF . Hence the average contribution of the bursts to the convection voltage is $(\Delta F/\Delta \tau)$.

Lockwood et al. [1990b] estimated the spatial dimensions of the events by assuming that the region of newly opened flux is convected past the meridian scanned by the EISCAT radar and the Svalbard photometers, without changing shape or size. From a survey of 12 events, they found that the events were typically 300 km in north-south extent, but were extended along the L shells, having a typical east-west dimension of 1500 km. Assuming a crude elliptically shaped patch, this yields an area of $A \approx 5 \times 10^{11} \text{ m}^2$ and a flux of $\Delta F \approx 2.5 \times 10^7 \text{ Wb}$. Magnetopause FTE observations typically last 2 min [Elphic, 1988], and if the events have not changed in size while moving between the reconnection X line and the satellite, this is the duration of the reconnection burst required (Δt). For this value, the mean reconnection voltage in the bursts is $(\Delta F/\Delta t) \approx 200 \text{ kV}$, but for the mean repetition period $\Delta \tau$ of 8 min, the average voltage over each cycle is $(\Delta F/\Delta \tau) \approx 50 \text{ kV}$.

High time resolution images of the 630-nm transients are

now available from a CCD all-sky cameras [e.g., Sandholt et al., 1990b, 1992a]. These images could be used to calculate the area of the events A if the emission profile and, in particular, the altitude of peak emission were known. The camera records the intensity of 630-nm emissions from a slant path along each azimuth and elevation. For an assumed emission altitude, h , an area can be computed for any region from the images obtained. However, the derived north-south and east-west dimensions and velocities of the events are all proportional to h , and the area A , flux ΔF , and the peak and average reconnection voltages are proportional to the square of h . Thus far, it has not been possible to make simultaneous observations of any one such event from two sites, and hence the emission altitude has not been determined empirically. From the foregoing, we conclude that accurate values of h are vitally important. This paper discusses the altitude from which the 630-nm transients arise and its implications. After a brief discussion of the uncertainty concerning the emission altitude in section 2, section 3 studies in detail two dayside breakup events, one moving eastward the other moving westward (as previously discussed by Lockwood et al. [1990c] and Sandholt et al. [1990b], respectively).

2. PROFILE OF 630-nm EMISSIONS

To date, no simultaneous observations of unambiguously the same 630-nm dayside auroral transient have been reported from two observing sites. Hence the emission altitude in these events has yet to be measured directly. Theoretically, there is considerable uncertainty over this height. It is interesting to note that in his pioneering work on triangulation measurements of the altitude of maximum auroral luminosity, Störmer [1955] recorded a considerable number of cases, where the peak luminosity was in the range of 300–500 km. In this section we discuss how significant 630-nm emissions could arise from great altitudes.

The major source of uncertainty in anticipating the height from which the 630-nm emissions will be most intense, derives from the variability of the electron gas temperature T_e . Very high values of T_e can elevate the altitude at which peak 630-nm emissions will occur to between 400–600 km. An appreciable source of uncertainty stems from variability in the fraction of the incident precipitating flux which is relatively soft (meaning of energy below roughly 100 eV). For instance, 25–100 eV electrons incident from above stop between 300–400 km altitude, while electrons with incident energies greater than 0.5 keV penetrate to below 200 km altitude. An additional consideration is that local thermospheric heating can lead to localized increases in the altitude of a given neutral atmospheric pressure level, as well as localized enhancements or depletions in density and changes in the O/N_2 density ratio by a few tens of percentage. Auroral workers generally assume a nominal 630-nm emission altitude near 250 km, based on the rapid increase of quenching much below that height, and the usual ratios of auroral electron fluxes near and above 1 keV to those around and below 0.1 keV. The above considerations mean that the height of a given peak 630-nm emission event in the cusp region of soft electron precipitation could be a factor of about 2 greater than the frequently assumed value of 250 km.

2.1. Precipitating Electron Impact Excitation

The 630-nm emission arises when an electron in the ^1D state of an oxygen atom falls to a lower energy level. The

altitude of excitation of this $O(^1D)$ state by precipitating electron impact is critically dependent on the energy of the incident electrons. This is because of the strong energy dependence of the collision cross sections, the consequent altitude of unity optical depth, and thus the depth of penetration of the incident electrons. Very soft electrons, with incident energies between 25–100 eV, are stopped between 300–400 km [Mantas and Walker, 1976]. This is the altitude range within which most of their energy deposition occurs and within which most of the associated $O(^1D)$ excitation occurs. For energies above 500 eV, most of the precipitating electron energy deposition (and $O(^1D)$ excitation) is below 200 km altitude. The efficiency of excitation of the $O(^1D)$ state, per unit incident energy, also depends on how hard or soft the incident electron flux is. Lower-energy electrons, which stop at higher altitudes where the O/N_2 density ratio is greater, lose their energy to air that is relatively oxygen rich. This leads to relatively more $O(^1D)$ excitation. The number of 630-nm photons emitted per $O(^1D)$ excitation is also significantly greater at higher altitudes. The long (about 2 min) mean lifetime of the $O(^1D)$ state of atomic oxygen gives deexcitation by collisions, before 630-nm photons are emitted. The density of N_2 , which is primarily responsible for this quenching the $O(^1D)$ state, falls with roughly twice the scale height of the O. More than 90% of the excited $O(^1D)$ yield 630-nm emissions near and above 350 km. This yield falls to an order of 10% near 225 km [e.g., Wickwar *et al.*, 1974] and continues to fall rapidly with decreasing altitude. Consequently, a given energy flux, carried by electrons soft enough to stop near 350 km, will be over 10 times as effective at producing 630 nm than if it had a sufficiently higher characteristic energy to penetrate to below 225 km.

The quenching is very severe below about 200 km, yet usually little impact excitation of the $O(^1D)$ state occurs above about 300 km. Consequently, researchers frequently assume an altitude near 250 km for the peak 630-nm emission at auroral latitudes. However, the high-altitude cutoff is, in fact, a consequence of the auroral electron energy spectrum. The intensity of the low (≤ 0.1 keV) energy portion of the precipitating electron energy flux, relative to the normally higher flux of the electron precipitation at higher energies, determines the decrease of the $O(^1D)$ excitation with increasing altitude. One should note that the electron precipitation in the cusp region typically consists of particles with energy that is lower than elsewhere in the auroral region; electron energies are generally tenths of a keV rather than the several keV found elsewhere in the auroral oval. Characteristic energies as low as tens of electron volts have been measured. The consequence for emission altitude is important. A decrease in characteristic energy to 20–30 eV from 200–300 eV can raise the 630-nm emission peak by about 100 km, yet it is not straightforward to characterize how representative such low energies may be of cusp precipitation in general. There is experimental difficulty in measuring electron fluxes with such low energies, because of variable spacecraft changing. However, Fontheim *et al.* [1987] concluded that the 1- to 10-eV component of the precipitation was greatly enhanced when very high ionospheric electron temperatures were observed by the DE 2 satellite.

It is widely agreed that electron precipitation leads to excitation of $O(^1D)$ and 630-nm emission by several processes and that direct electron impact excitation by second-

ary electrons or by very low energy primaries are not the only mechanisms [e.g., Rees and Roble, 1986]. This is largely because the $O(^1D)$ excitation threshold is so low (1.96 eV). However, for our purposes it is sufficient to note that with the exception of the thermal electron excitation term discussed in the next section these all peak at comparable altitudes. This altitude is near the neutral pressure level of unity optical depth for the characteristic energy of the incident auroral electrons in question. Note that an intense flux of soft auroral electrons will lead to rapid heating of the electron gas on the same flux tubes as the auroral electron impact emission. Thus the precipitating electrons produce both thermal and impact excitation on the same flux tube. However, the emission altitude for the thermal excitation is, potentially, much higher than for the impact excitation.

2.2. Thermal Electron Excitation

Because $O(^1D)$ has such a low threshold of energy excitation (1.96 eV), it can be excited by the high-energy tail of a thermal electron gas of sufficiently high temperature. The steep increase of excitation cross section with energy just above 2 eV, make the thermal electron impact component of 630 nm critically dependent on the electron gas temperature, T_e . As T_e increases from 2000 to 4000 K, the rate of $O(^1D)$ excitation increases by $2\frac{1}{2}$ orders of magnitude. The absolute 630-nm emission rate depends on the number of thermal electrons, times the number of atomic oxygen atoms with which they could collide, with allowance for quenching. For representative conditions in the cusp, an increase in T_e at 500 km from 3000 K to 4000 K, causes a tenfold increase in the 630-nm emission, from an order of 0.1 kR to an order of 1 kR.

Indirect experimental evidence supports the suggestion that thermal excitation can be important in the cusp. Electron gas temperatures which were sufficiently high to excite significant 630-nm emission have been measured at Sondrestromfjord, [Wickwar and Kofman, 1984], on the Dynamics Explorer 2 [Brace *et al.*, 1982], and over Svalbard, as viewed by EISCAT by the Polar Experiment (see section 3.2).

A theoretical or modelling consideration of the intensity and altitude of this thermally excited 630-nm emission is, essentially, an electron gas thermal balance consideration. The question is whether we should expect a sufficiently high T_e at an altitude where a sufficiently great electron concentration N_e coexists with a sufficiently large atomic oxygen concentration, such that the rate of collisional excitation of $O(^1D)$ will lead to 630-nm emission with kilorayleigh intensities.

It is beyond the scope of this paper to carry out a full thermal balance computation. However, a discussion of the processes and order of the terms prove most useful. The reader is referred for a full quantitative analysis to a parametric study of specific absorption rate arcs by Kozyra *et al.* [1990]. Much of the physics applicable to SAR arcs can be applied to the dayside 630-nm transients, aside from the different source of the electron gas heating. We here give a simple qualitative description of the important points.

At the onset of a flux of precipitating electrons, into the optically thin topside ionospheric electron gas (of density N_e), the ambient electron gas temperature T_e will start to increase at all altitudes. The initial rate of increase will depend on the incident electron flux but not on N_e (the

collision cross section and the heat capacity both increase with N_e , and their effects tend to cancel). A flux of electrons of energy of order tens of electron volts, which is intense enough to produce 630-nm luminosity of the order of Kilorayleigh intensity, will initiate a T_e increase at a rate of about 10^3 K per minute. This is an upper limit that neglects subsequent electron gas energy loss. Since background magnetospheric electron heat fluxes maintain T_e values near 500 km of 2000–3000 K in quasi-steady state, the electron gas cooling rate is a key consideration.

For low-electron densities ($N_e < 3 \times 10^5 \text{ cm}^{-3}$) and temperatures ($T_e < 3 \times 10^3$ K), the electron gas cools mainly by electron gas heat conduction down magnetic field lines. Near about 200 km, electron-neutral collisions maintain the electron gas in close thermal contact with the neutral particle gas. Thus T_e decreases monotonically with decreasing height and the shape of the altitude profile of T_e is essentially given by the heat conduction equation. In equilibrium, the T_e gradient at any height is just that which conducts heat downward at the rate which heat conducts from above, less the local volume cooling or heating rate. Thus the greater the heat flux, the greater the T_e and altitude gradient of T_e at any height.

The rate of electron gas cooling to the ion gas (that is, the rate of decrease of energy density of the electron gas) is proportional to the number of electrons available for collisions, times the number of ions available to collide with, that is, to N_e^2 . The rate of decrease of the electron temperature T_e is therefore proportional to N_e . Near the height of maximum N_e , h_{max} , the electron cooling by this mechanism depends critically on N_e . Specifically, cooling to ions is unimportant for N_e much less than about $3 \times 10^5 \text{ cm}^{-3}$, whereas it is dominant for N_e considerably greater than this value. Thus the value of maximum N_e determines whether T_e is reduced to the neutral gas temperature near 200 km or is just reduced to the ion temperature near the greater altitude of h_{max} . This has great implications for whether T_e near 400–500 km can approach high enough values to thermally excite 630-nm emission or is drawn down much closer to the thermospheric temperatures, which would not yield such strong thermal excitation of the $\text{O}(^1\text{D})$ state. Examination of the quantitative modeling by Kozyra *et al.* [1990] reveals the following simple argument. When T_e at h_{max} is near 4000 K, and values of N_e are high enough to expect dT_e/dh to be about 5 K/km, 630-nm luminosity of an order of kilorayleigh intensity will arise near 500 km, especially when the altitude of maximum N_e , h_{max} , is near or above 350 km.

We can summarize the foregoing discussion with three broad statements.

1. When the characteristic energy of the auroral precipitating electrons exceeds 0.6 keV, a peak 630-nm emission near, or a little below, 250 km is expected.
2. When the characteristic energy is 25–100 eV, the emission altitude may be expected to be between 300 and 400 km.
3. When T_e exceeding 3500 K is present near 400–500 km, peak emission altitudes near 500 km are expected, especially when the T_e altitude gradient is large and the F_2 peak is at high altitudes.

2.3. Mapping 630-nm Luminosity

Figure 2 shows the implications of the emission altitude for the deduced latitude of the luminosity for observations

Fig. 2. The invariant latitude Λ as a function of zenith angle at Ny Ålesund, χ , (defined as positive to the north) for the magnetic meridian scanned by the photometers. Plots are shown for the possible 630-nm emission altitudes of $h = 250, 300, 350, 400, 500,$ and 600 km as well as for the possible 557.7-nm emission altitudes of 110 and 130 km.

along the magnetic meridian through Ny Ålesund, Svalbard. The plot shows the invariant latitude, as a function of the zenith angle χ , defined as positive to the north. The values have been calculated using the International Geomagnetic Reference Field model, with constants appropriate to 1989. The plot is for the same azimuth as employed by the meridian-scanning photometers at Ny Ålesund, namely 29.5° west of north for $\chi > 0$ (and 150.5° east of north for $\chi < 0$). Figure 2 shows the curves for various values of the emission altitude h ; as discussed above, the curves for 250–600 km are relevant to the 630-nm emissions. Also shown are the curves for h of 110 km and 130 km, which cover the expected range of emission altitudes for the 557.7-nm aurora. All curves show approximately the invariant latitude of Ny Ålesund (75.8°) at χ of -7° , when the instrument points up the field line. Away from this direction, the invariant latitude deduced for a given observation is strongly dependent on the emission altitude assumed. It can be seen that the likely variations in the altitude of the 557.7-nm emissions cause very little variation in the derived invariant latitude, especially at zenith angles below 45° . As most of the 557.7 nm discussed here was taken at χ below this value, these differences are here neglected and all 557.7-nm emissions mapped with an assumption of $h = 110$ km.

Naturally, 630-nm emissions will, in practice, arise from a considerable range of altitudes around the height of peak emission. This spread will have little effect on the inferred latitude of the edge of a patch of 630-nm luminosity, provided that edge is close to zenith.

However, the spread in altitudes causes two effects at greater magnitude of the zenith angle. Emissions from below the altitude of peak emission will cause some luminosity to appear to arise from further away from the optical instrument than is really the case, if the data are analyzed assuming all luminosity comes from the peak emission height. However, the instrument records the intensity of 630-nm emission, integrated along the slant path through the feature, and this will increase continuously with decreasing $|x|$ for those slant paths which intersect the edge of the 630-nm patch. Hence the latitude of the edge derived will depend on the 630-nm isophote (intensity contour) chosen to delineate the feature in question. Depending on that choice of isophote, the latitude of the edge derived can be greater or smaller than that derived by the simple assumption of a single emission altitude. The precise magnitude of this uncertainty depends upon the three-dimensional distribution of emission rate and on the relative locations of the instrument and the luminosity.

3. OBSERVED EXAMPLES OF DAYSIDE BREAKUP EVENTS

3.1. A Westward Moving Event on January 12, 1988

This event has been presented and discussed by Sandholt *et al.* [1990b] and Lockwood *et al.* [1989b], and the reader is referred to these papers for a detailed description of the event and a full presentation of the data. In this section, we reanalyze the meridian-scanning photometer data, using the mapping curves shown in Figure 2, as will also be done for an event on January 9, 1989, in the following section. Images from the 630-nm charged-couple device camera were not available for this day.

This event was revealed to be moving westward by the intensifier-silicon-intensifier target all-sky camera (mainly sensitive to 557.7-nm light) and by the EISCAT radar flow measurements. This motion was consistent with the event being on newly opened field lines as the IMF B_y component was measured to be strongly positive at this time. Note B_y also showed very little variation, so the event does not simply represent the effects of an increase in IMF B_y for a constant magnetopause reconnection rate.

Meridian-scanning photometer data. Figure 3 analyzes the northward motions of the peak intensity of various features observed by the meridian-scanning photometers during this event. The solid lines show the latitudes of the transient 557.7-nm auroral forms as a function of time, mapped using the assumed emission altitude of 110 km. All show a fluctuating poleward motion the speed of which initially averages 0.63 km s^{-1} , which would give the straight dashed line. The dashed data curve shows a 630-nm transient near zenith which has been mapped for an emission altitude of 250 km. The dot-dashed curves are for the peak of the main 630-nm transient. This has been plotted for three assumed values of h . For the higher two (400 and 550 km) the red-line emissions have a mean lifetime of $\tau = 110 \text{ s}$. Hence to allow comparison with the 557.7-nm emissions ($\tau = 3/4 \text{ s}$), the 630-nm plots have been shifted along the time axis by this lifetime, such that the plots attempt to show the time at which the oxygen atoms were excited, rather than the time at which they emit the 630-nm photon. For any curve for which the assumed value of h is 250 km, the lifetime τ has been reduced to 55 s. This is because quenching of 630-nm emissions is important at this lower altitude. The excited

Fig. 3. The invariant latitude, Λ , as a function of UT of various features observed by the meridian scanning photometers during the second event on January 12, 1988 [see Lockwood *et al.*, 1989b, Figure 2]. The solid lines are for the peak emission of 557.7 nm, mapped assuming an emission altitude, h , of 110 km. The dashed data curve is for the 630-nm transient observed near zenith, mapped for an assumed emission altitude of 250 km. The dot-dashed curves are for the peak of the main 630-nm transient event, mapped for h of 250 km, 400 km and 550 km. In all cases, the 630-nm forms have been mapped at the predicted time of excitation of the oxygen atoms, a time τ before the observation time. For h of 550 km and 400 km, τ is taken to be 110 s, but for h of 250 km, τ is reduced to 55 s to allow for quenching. The straight dashed line shows the locations for features moving poleward at a constant speed of 0.63 km s^{-1} .

states which deexcite by collisions will tend to be those which have the higher values of the distribution of lifetimes. Hence the states which do emit will tend to have shorter lifetimes and the mean (τ) will be lower. Hence a τ of 55 s has been used for an emission altitude of 250 km, where collisions are much more prevalent.

Comparison of the deduced motion of the main 630-nm transient, shown in Figure 3 for the three assumed emission altitudes, reveals that it would be moving north more rapidly than the 557.7 nm for the higher two of the altitudes presented. This is not the behavior predicted by Figure 1. On the other hand, the 250-km altitude gives a poleward speed which matches that of the 557.7-nm transient well, which is consistent with Figure 1.

Figure 4 analyzes the relative locations of the transient aurorae during this event, by plotting the emission intensity I as a function of invariant latitude. The dashed curve shows the 557.7-nm emissions for the scan commencing at 0921:30 UT, whereas the other two curves are for 630-nm emissions. The solid curve was recorded at 0922:24 UT and hence can be compared with the dashed curve if the mean lifetime of the excited oxygen atom is $\tau = 56 \text{ s}$. This is roughly

Fig. 4. The intensity I of transient emissions over and to the south of Ny Ålesund as a function of invariant latitude Λ for the event on January 12, 1988, addressed by Figure 3. The dashed line is the 557.7-nm emissions observed at 0921:30 UT and mapped assuming $h = 110$ km. The solid line is the equivalent 630-nm emissions for an assumed emission altitude of $h = 250$ km (observed at the time 0922:24 UT, that is, for a deexcitation lifetime τ of 56 s) and the dot-dashed line is that for $h = 550$ km (observed at 0923:18 UT, that is, for $\tau = 110$ s). The dotted line shows the latitude profile of the ion temperature observed by azimuth 2 of the EISCAT Polar Experiment over the integration period 0922:20–0924:30.

consistent with an emission altitude of 250 km, which is the value used to map the data onto the invariant latitude scale. The dot-dashed curve shows the data recorded in the scan commencing 0923:18 UT, which was mapped assuming an emission altitude of 550 km (which can be compared with the given green-line latitude profile if $\tau = 110$ s.)

The dashed line shows a very strong peak on the poleward edge of the 630-nm transient. This is true irrespective of the altitude from which the 630-nm light is assumed to have originated. The solid line shows a secondary peak very close to this narrow 557.7-nm feature, suggesting that this 630-nm emission originated from a low altitude on the same field line. Equatorward, the latitudinal extent of the 630-nm event depends greatly upon the assumed emission altitude. For 250 km the event ($I > 1$ kR) extends to about 72° , whereas for 550 km, it reaches 68.5° . It should be noted that in the poleward half of the mapped 630-nm emission (for either altitude) there is some 557.7-nm emission, of peak intensity about one third of that for the narrow feature on the poleward edge. Figure 4 illustrates how sensitive the derived extent of the 630-nm transient is to the assumed emission altitude.

EISCAT radar data. For both of the events discussed in this paper, the EISCAT radar was operating in the Polar Experiment mode. This beam-swinging mode employs a beam elevation of 21.5° and two azimuths of 332° and 356° (east of geographic north at Tromsø, T), termed azimuths 1 and 2. These beam directions are plotted on the map shown in Figure 5. It can be seen that azimuth 2 passes close to the east of the Ny Ålesund and is at a reasonably small angle to the photometer direction. The radar employs a 5-min cycle, dwelling 130 s at each azimuth and taking 20 s to swing between them. Hence the entire cycle lasts 5 min.

The dotted line in Figure 4 shows the ion temperature as a function of invariant latitude, as observed along the azimuth 2, for the dwell that is closest in time to the photometer scans

Fig. 5. Map showing the two beam directions of the EISCAT Polar Experiment, relative to the fields of view of the optical instruments at Ny Ålesund, Svalbard (NÅ). The data used in this paper were recorded at Tromsø (T) and are for the beam segments shown as thick solid lines. The circles show the zenith angle contours for $\chi = 60^\circ$ (that is, the second concentric circle in Plate 1). The solid circle is for the ISIT camera which is largely sensitive to 557.7-nm light, which is assumed to originate from an altitude h of 110 km. The dashed and dot-dashed circles are for the CCD camera, sensitive to only 630-nm light, for h of 250 and 500 km, respectively. The straight dot-dashed line is the meridian scanned by the photometers.

TABLE 1. Inferred Plasma Velocities for 0922:20–0924:30 UT on January 12, 1988

Gate Number	Invariant Latitude, deg	T_i , K	V_{los}	V_i , km s ⁻¹	V_n	V_w
3	72.0	1403	0.20	0.88	0.37	0.80
4	72.6	2108	0.36	1.37	0.63	1.22
5	73.2	3400	0.20	2.00	0.61	1.91
6	73.8	6149	0.24	2.85	0.63	2.78
7	74.3	8000	0.17	3.30	0.85	3.19
8	74.9	6000	-0.09	2.80	0.57	2.74

shown. The spectra have here been analyzed with allowance for the non-Maxwellian nature of the ion velocity distribution. This can greatly influence the ion temperature derived when the ion drift is large, particularly for the low beam elevation employed here [Lockwood and Winsor, 1988]. This analysis was carried out using the procedure described by Suvanto *et al.* [1989]. The large drifts in the events mean that distortions of the ion distribution function were observed at this time [see Lockwood *et al.*, 1989c].

The ion temperature variation shows a clear peak of near 7500 K at around 74.5° and is at much lower values, close to the estimated thermospheric temperature of 900 K [Lockwood *et al.*, 1989c], at 71.5°. The increase in ion temperature is at latitudes above 72°. For the pulsating cusp model the cusp particles precipitating down newly opened field lines produce 630-nm emissions, while the ion temperature is simultaneously raised by the large drifts (due to the magnetic tension experienced by the field lines if the IMF B_y component is large, as in this example). Hence for this case, the similarity of the latitude profiles of the ion temperature and the 630-nm intensity for $h = 250$ km also suggests that this is the true emission altitude.

Table 1 presents an analysis of the plasma velocities in this event. This analysis is not based on the beam-swinging technique, but rather on the ion temperature and the line-of-sight velocity (V_{los}) observed at azimuth 2, close to the photometer meridian. The ion temperatures derived for the western azimuth (1) are very similar to those for this eastern one (2) throughout this event. Hence the beam-swinging assumption that the flow is uniform between the azimuths may remain reliable in this case (this is certainly not true for the other event described in the next section). However, here we will simply use the beam-swinging data to infer that the flow along the L shells was westward and fast enough for the neutral wind speed and the electron-ion term (and all higher-order terms) in the ion heating equation to be neglected. Under such conditions, we can estimate the magnitude of the ion velocity V_i from the simplified ion energy balance equation, as given by Lockwood *et al.* [1990c, equation (1)]. Given that the component of the flow normal to the radar beam is westward, this can be combined with V_{los} to derive the northward and westward components of the plasma velocity V_n and V_w , respectively. Table 1 shows that the northward flow derived this way is, for all gates, close to the value of about 0.6 km s⁻¹ inferred for the optical transients (both the 557.7-nm transient and the main 630-nm transient for emission from 250 km; see Figure 3). The peak westward flow speed of 3 km s⁻¹ is very similar to the westward motion of the 557.7-nm transient, as derived from the ISIT all-sky camera at this time [Sandholt *et al.*, 1990a].

Hence the transient auroras are moving with the plasma flow, which is consistent with the flux transfer event model.

3.2. An Eastward Moving Event on January 9, 1989

In this section, we consider a second transient event observed at almost the same MLT as that reported in the previous section (in fact just 20 min earlier) on January 9, 1989. This event has been presented and discussed by Lockwood *et al.* [1990c], and the reader is referred to that paper for presentations of the photometer data and 557.7-nm images. However, Lockwood *et al.* [1990c] did not include the sequence of 630-nm images, as observed by the CCD camera, which is discussed here. The main difference between this event and the previous one is that the images show it to be moving eastward. Simultaneous IMF data are not available for this event; however, similar eastward moving events on other days have been shown to be for $B_y < 0$ [Sandholt *et al.*, 1992a, b].

630-nm all-sky camera data. The relative intensity detected by the CCD all-sky camera at Ny Ålesund, with a 630-nm filter, is shown in the all-sky images of Plate 1. These are 1-s integrated images, 2.5 min apart. The second concentric circle is the zenith angle contour for 60°, the location of which for assumed emission altitudes is given in Figure 5. The sequence starts with a dayside transient event commencing at 0834:00 UT near the western horizon and moving rapidly eastward. This event fills most of the poleward half of the imager field-of-view at 0844:00 UT, and the trailing edge propagates eastward during the period 0846:30–0854:00. One should note that the sensitivity of the camera falls rapidly with zenith angle between 60° and 90°, and hence at the peak of the event the camera does not define its full east-west extent.

The onset of the second event is not observed because of the data gap at 0901:30 UT, but it fills the northern half of the field of view at 0904:00 (20 min after the previous event was at a similar phase of its evolution). The trailing edge of the second event then moves eastward in the same manner as the first event. A smaller third event is underway by the end of the sequence at 0929:00 UT. If we compare the images at 0854:00 UT and 0914:00 UT, we find that the first and second events are then at a similar phase of their evolution near the eastern limb of the field-of-view, confirming the cycle time of about 20 min for these events. It is interesting to compare this sequence with that presented by Sandholt *et al.* [1992a] which revealed less extensive events, however, with a lower repetition period of about 8 min.

This sequence could be interpreted as showing a relatively stable red-line arc to the south of Ny Ålesund, with transient forms coming and going to the north of the site. However, we note that the background arc brightens and fades considerably at times, particularly to the west and hence is in reality far from steady and stable.

Table 2 considers the eastward motion of the 630-nm transient event on January 9, 1989, as derived by comparing successive images of the sequence. The clearest propagating feature is the trailing edge of the event, and the position of this is determined along the invariant latitude of 76° for each image in which it is defined. The derived velocity of the event is initially 1.1 km s⁻¹ for an assumed emission altitude of $h = 250$ km. This value rises to 2.5 km s⁻¹ for $h = 550$ km. These speeds are averages which apply to the period 0904:30–0909:00 UT.

TABLE 2. Eastward Motion of Trailing Edge of 630-nm Transient on January 9, 1989

UT	χ , deg	$h = 250$ km	V_e , km s ⁻¹ $h = 400$ km	$h = 550$ km
0904:30	57 W			
0905:30		1.125	1.800	2.475
0906:30	45 W			
0907:45		1.125	1.800	2.475

0914:00	27 E			

Meridian-scanning photometer data. Figure 6 analyzes the northward motions of the peak intensity of various features observed by the meridian-scanning photometers, during the second of the events shown by the sequence in Plate 1. As in Figure 3, the solid lines show the latitudes of the transient 557.7-nm auroral forms as a function of time, mapped using the assumed emission altitude of 110 km. All show a relatively steady poleward motion at about the same speed as the event studied in the previous section. For comparison purposes, the straight dashed lines give the same poleward speed of 0.63 km s^{-1} as in Figure 3. Hence the two events studied in this paper are very different in their east-west motion but move poleward at a similar speed which is around 0.6 km s^{-1} . The dashed data curve shows a 630-nm transient near zenith which has been mapped for an emission altitude of 250 km, because it appears to be collocated with the 557.7-nm transients.

The dot-dashed curves are for the peak of the main 630-nm transient. This has been plotted for the same three assumed values of h as used in Figure 3 for the westward moving event. The same relationship between the lifetime of the excited state and the emission altitude has been applied. Figure 6 shows that the poleward motion of the 630-nm transient matches that of the other transient aurora if the emission altitude is higher rather than lower, given that the average poleward motion appears to be too slow for the lowest of the altitudes shown (250 km). However, we cannot state the altitude with certainty because the errors in this comparison are great.

Figure 7 analyzes the relative locations and intensities of the transient aurorae by plotting the emission intensity as a function of latitude for the northern part of the scan. (In the southern part of the scan a second 630-nm peak is observed, which from the stacked photometer plots [see Lockwood *et al.*, 1990c] can be interpreted as either a continuation of a steady background or the next in the series of poleward events forming). As in the corresponding plot for the westward moving event on January 12, 1988 (Figure 4), the dashed curve shows the 557.7-nm emissions (for the scan commencing at 0902:49 UT), whereas the other two curves are for 630-nm emissions. The solid curve was recorded at 0903:43 UT, and hence can be compared with the dashed curve if the mean lifetime of the excited oxygen atom is $\tau =$

Fig. 6. The invariant latitude Λ of various features observed by the meridian-scanning photometers during the event on January 9, 1988, shown in Plate 1. The plot format is the same as for Figure 3. The straight dashed lines show the locations for features moving poleward at a constant speed of 0.63 km s^{-1} (the same as Figure 3 to allow comparisons).

56 s. This is roughly consistent with an emission altitude of 250 km, which is the value then used to map the data onto the invariant latitude scale. The dot-dashed curve shows the data recorded in the scan commencing 0904:39 UT mapped assuming an emission altitude of 550 km. (This can be compared with the shown green-line latitude profile if $\tau = 110 \text{ s}$.)

For either of the assumed emission altitudes we find that the 557.7-nm transient lies on the equatorward edge of the eastward moving transient 630-nm form. Hence this is consistent with Figure 1b, in which case we would interpret the 630-nm peak to the south of zenith as the cleft and the transient form poleward of the 557.7-nm arc as the cusp. It should be noted that the 557.7-nm arc is here shown as being about 0.5° wide (equivalent to about 60 km). This may be an overestimate of the true width because, for the large zenith angle at which it was detected, the apparent width will have been increased by any spread in altitudes from which the 557.7-nm light is emitted. On the other hand, the red-line transient is 3 times wider for $h = 250 \text{ km}$ and is 6–7 times larger for $h = 550 \text{ km}$.

Plate 1. (Opposite) A sequence of 1-s all sky camera images recorded from Ny-Ålesund on January 9, 1989 using the 630-nm emission line. The images shown are 2.5 min apart. Each plot shows the zenith angles χ of 30° and 60° as complete concentric circles and the 90° circle can be seen in the top right (northeast) corner of each frame. The perpendicular crossed lines are the geographic north-south and east-west directions and the single diagonal line is the magnetic meridian scanned by the photometers (see also Figure 5).

Fig. 7. The intensity I of transient emissions to the north of Ny Ålesund as a function of invariant latitude Λ for the second event on January 9, 1989, shown in Figure 6. The dashed line indicates the 557.7-nm emissions observed at 0902:49 UT and is mapped assuming $h = 110$ km. The solid line is the equivalent 630-nm emissions for an assumed emission altitude of $h = 250$ km (observed at the time 0903:43 UT, that is, for a deexcitation lifetime τ of 56 s), and the dot-dashed lines are for the peak of the main 630-nm transient for $h = 250$, 400, and 550 km (the latter two were observed at 0904:39 UT, that is, for $\tau = 110$ s).

EISCAT radar data. Evidence supporting the idea that the transient 630-nm emissions may arise from the greater altitudes comes from comparing the EISCAT radar data with the images shown in Figure 5. Plate 2a shows the ion temperatures observed during these events, whereas Plate 2b shows the line-of-sight velocities and Plate 2c shows the observed electron temperatures. The plot shows data from both of the two azimuths of the radar experiment, which are addressed in turn in the 5-min beam-swinging cycle. Periods when the antenna is in motion show up as white strips. The first latitude profile shown is for the easterly azimuth 2, as is every other profile thereafter. These alternate with the data from the other, westerly azimuth (1). The first event seen by the optical instruments corresponds to the rise in ion temperatures around 0845 UT, the equatorward edge of which then propagates poleward out of the radar field of view. The second event causes a more major event between about 0902:30 and 0925:00 UT. The radar beam direction close to the center of the Ny Ålesund camera field of view (azimuth 2) observes greatly elevated ion temperatures commencing at 0902:30 UT, which move poleward at both azimuths and at an average of 0.65 km s^{-1} . This ion heating is within the radar field of view until after 0915:00 UT. Because the transient feature is further from the radar than the January 12, 1988, case, these high ion temperatures are observed at a

much greater altitude (over 550 km), for which ion-ion collisions are expected to destroy the non-Maxwellian distortions and anisotropy of the ion velocity distribution [Tereschenko *et al.*, 1991], as were observed at lower altitudes in the event on January 12, 1988. Indeed, analysis of the radar spectra using the non-Maxwellian procedure reveals no non-Maxwellian distortion, despite the exceedingly high ion temperatures and large aspect angle of the observations. Hence we assume that the derived line-of-sight ion temperature is the three-dimensional ion temperature which is used in the ion energy balance equation [Lockwood and Winsor, 1988].

The high ion temperatures observed at azimuth 1 in the period 0902:30–0907:30 UT are over 6000 K, compared with an estimated neutral temperature of 1250 K. From the ion energy balance equation, this requires an ion drift of about 2.7 km s^{-1} at this azimuth [see Lockwood *et al.*, 1990c]. Such greatly elevated ion temperatures are not observed in the azimuth 2 at these times, and hence the beam-swinging technique cannot give reliable vectors because the flow is so spatially structured within the EISCAT field-of-view: the technique is therefore not used here. Table 3 presents an analysis of the flow at azimuth 2 using the same procedure as applied to the January 12, 1988 event in Table 1. From the ion temperatures when the ion drift is low, the thermo-

Plate 2. (Opposite) EISCAT radar data on January 9, 1989: (a) the ion temperatures, T_i , and (b) the line-of-sight velocities v_{los} and (c) the electron temperature T_e . Data are shown for both azimuths used by the SP-UK-POLH experiment (332° and 356° east of geographic north from Tromsø) which are viewed alternately in a 5-min beam-swinging cycle. The white strips mark the times when the antenna is in motion.

TABLE 3. Inferred Plasma Velocities for 0905:30–0907:40 UT on January 9, 1989

Gate Number	Invariant Latitude, deg	T_i , K	V_{los} , km	V_i , km	V_n , km	V_w , km
15	75.38	2301	0.84	1.28	0.62	-1.12
16	75.64	2725	0.88	1.50	0.60	-1.37
17	75.90	3807	0.95	1.99	0.57	-1.91
18	76.16	4127	0.98	2.11	0.57	-2.03

spheric temperature employed is 1250 K. Table 3 only shows those latitudes for which the ion temperature and the signal-to-noise ratio are both sufficient to allow this calculation to be made. Comparison with Figure 7 indicates that the radar observed the eastward flow speed increasing as the latitude increased toward the location of the 557.7-nm transient. Table 3 shows the northward plasma velocity is always close to the 0.6 km s^{-1} calculated from the transient auroras in Figure 6. The eastward flow speed on the equatorward edge of the event is of the order of 2.0 km s^{-1} and is probably greater than this at the latitude of the peak of the 630-nm transient (77.5° and 80.0° for emission altitude of 250 and 550 km, respectively, both beyond the radar field of view).

Hence we find that the northward motion of the main 630-nm transient is consistent with that of the 557.7-nm transients and the same as the poleward plasma flow deduced from EISCAT, if the peak 630-nm emission is at an altitude of 550 km. Furthermore, comparison of Tables 2 and 3 shows that the eastward event motion and the eastward plasma flow are the same if the emission altitude is somewhat greater than 500 km. For the transient reconnection model of these events, the optical features should move with the same flow speed as the plasma within them. This has been found to be true for the strong 557.7-nm arcs observed moving westward. However, it is only true for the 630-nm arcs observed here moving eastward if the emission comes from an altitude of at least 500 km, and 550 km is the best estimate. Given the uncertainties in this comparison, we regard 400–500 km, as the most likely range of values for the peak emission altitude, but we note that this may be a somewhat conservative estimate as the height is more likely to be above 500 km than it is to be below 400 km. An altitude of 500 km would give an event (and hence plasma) speed of 2.4 km s^{-1} and an ion temperature within the event of at least 5000 K. Plate 2a shows such temperatures were frequently observed in this event.

For the time period of concern in Figure 6 (January 9, 1989, 0900–0904 UT), measurement of T_e by the radar, near 78° invariant latitude, involves error bars too large to serve as a direct test for thermal excitation of 630-nm emission around 400–500 km. At this latitude, even if the error bars were small, interpretation would be complicated by the need for extrapolation of T_e from the measurement altitude of about 680 km down the magnetic field line to 400–500 km. However, good quality data were obtained up to 76.9° invariant latitude at 0855:30–0857:30 UT. Examination of those data shows a latitude at and above which T_e was sufficiently high to meet the criteria discussed in section 2 for high-altitude thermal excitation of the $O(^1D)$ state and hence 630-nm emission. The maximum T_e observed exceeded 4000 K, at 76.3° Λ and at 550 km altitude. Strongly enhanced

plasma drift velocity, as evidenced by T_i and line-of-sight velocity enhancements, was measured 1–2 range gates further north (76.6° – 76.9° Λ). Extrapolating the T_e peak northward at the inferred drift velocity of 0.6 km s^{-1} , tracks the 630-nm enhancement on Figure 6 at an altitude of about 400–500 km. While certainly not proof, this consistency between the location of the extrapolated T_e peak and that estimated for the observed 630-nm enhancement, again reinforces the case for a high source altitude of this 630-nm emission. It is interesting to note that for the other event discussed in this paper (January 12, 1988, around 0920), the observed T_e was well below the threshold for any significant thermal excitation of 630 nm. Hence the above considerations are again consistent with the altitude of the 630-nm enhancement estimated from the motions of the transients; however, in the January 12, 1988, case that altitude is near 250 km, whereas in the January 9, 1989, case it is probably in the range 400–500 km. The emission altitudes inferred for January 9, 1989, are slightly, but not greatly, greater than the value of 400 km derived from Sondrestromfjord data by Wickwar and Kofman [1984] for slightly more intense emissions.

4. IMPLICATIONS OF THE HIGH-EMISSION ALTITUDE

As discussed in the introduction, estimates of the reconnection voltage in, and of the contribution to the averaged transpolar voltage of, these events vary as the square of the assumed emission altitude.

On January 12, 1988, the emission altitude appears to be relatively low, that is, around 250 km. This yields a north-south extent of the 630-nm transient of about 300 km. This is the same as derived from the radar flow measurements by Lockwood *et al.* [1990b]. The 630-nm transient persists for over 400 s, and the radar data show that the peak westward flow at the center of the transient 630-nm region of 3.2 km s^{-1} (see Table 1) is maintained for this period. This yields an east-west dimension for this event of 1300 km and, for a simplistic elliptical shape, an area of $A = 3 \times 10^{11} \text{ m}^2$ and a flux of $\Delta F = (A)B_i = 1.5 \times 10^7 \text{ Wb}$. Note that an ellipse is used here only to give a crude estimate of the area: Figure 1 illustrates that the true shape of the event will evolve during the events lifetime. For the reconnection time $\Delta t = 2 \text{ min}$ discussed in the introduction, the reconnection voltage $(\Delta F/\Delta t)$ is 125 kV. This event follows another at an interval Δt of about 10 min; hence the contribution to convection is $(\Delta F/\Delta \tau) = 25 \text{ kV}$.

Images of 630-nm emission, like those shown in Plate 1, would give a much more satisfactory way to determine both dimensions of the 630-nm events, if the emission altitude were known. Here we shall consider the voltages for the January 9, 1989, event using small and large values for h of 250 and 500 km. Given that the analysis presented in section 3.2 indicates that the main 630-nm peak arises from closer to the greater of these two values than the smaller, we infer that the larger values will be the more applicable to this event.

From Figure 7, the 630-nm transient, observed poleward of the 557.7-nm feature at 0904:39 UT has a north-south extent of 640 km for $h = 500 \text{ km}$ and 320 km for $h = 250 \text{ km}$. At this time (0904:30 UT) the event can be seen in Plate 1 to extend along the Ny Ålesund L shell from a zenith angle of about $\theta_1 = 60^\circ$ to the west and at least $\theta_2 = 75^\circ$ to the east. This is a minimum estimate as the camera has very little

sensitivity for zenith angles greater than this. The east-west extent is $h(\tan \theta_1 + \tan \theta_2)$, which is therefore a huge 2750 km for $h = 500$ km, but only 1375 km for $h = 250$ km. Again, using an elliptical shape for simplicity, we derive areas of $1.4 \times 10^{12} \text{ m}^2$ and $3.4 \times 10^{11} \text{ m}^2$ and corresponding magnetic fluxes of $6.8 \times 10^7 \text{ Wb}$ and $1.7 \times 10^7 \text{ Wb}$, respectively. From the images we observe this patch to chiefly grow in the interval 0858:30–0904:30 (that is, $\Delta t = 6$ min), which yields a reconnection voltages ($\Delta F/\Delta t$) = 188 and 47 kV. In addition, the period between events is here $\Delta \tau = 20$ min for which the contributions to average convection would be ($\Delta F/\Delta \tau$) = 56 and 14 kV (for the emission altitudes of 500 and 250 km, respectively).

These estimates may be either increased or decreased depending on our choice of 630-nm isophote which delineates the event and hence are highly approximate. This uncertainty arises from locating the edge of the event with an assumed single emission altitude when in practice the light comes from a range of altitudes, as discussed in section 2.3. However, these calculations illustrate the importance of knowing the peak emission altitude if not the full emission profile. The value of 14 kV derived for the lower altitude of 250 km is only about 10% of the voltage observed across the polar cap during strongly southward IMF. However, the voltage of 56 kV derived for the higher emission altitude is about half this typical value. Hence the questions about the importance of these events for convection call for accurate determination of the altitude profile of emission. The corresponding value for the January 12, 1988, event is well defined by the joint optical/radar observations to be around 25 kV.

It is interesting to compare these values with those for events recently reported by Sandholt *et al.* [1992a]. These events were smaller (and hence could be fully imaged by the CCD camera) but were repeated with an average period of 9 min. Assuming an emission altitude of 250 km, these authors derived event dimensions of 200 km north-south by 300 km east-west. For these values the average contribution to convection is just 4 kV. This would rise to a maximum of 20 kV if the 630-nm emission were in fact from an altitude of 550 km.

5. CONCLUSIONS

We have examined two dayside auroral transients and associated flow burst events. Although both have been previously published, we have examined them more critically here for the purpose of making three important points.

The first point is to verify the symmetric consistency of our electrodynamic description of the transient events. In both eastward and westward propagating cases, the 557.7-nm transient (produced by energized electron impact excitation) is a latitudinally narrow feature collocated with the inferred transient upward field-aligned current. This means for these northern hemisphere events that the 557.7-nm transient lies on the equatorward edge of the flow burst and the 630-nm transient for the eastward moving event but on their poleward edge for the westward moving event. The flow burst and 630-nm transient are collocated in both cases and the plasma flow within the burst, as deduced from the radar observations of ion temperature and line-of-sight velocity, has been shown to be very similar to the auroral event motion.

The observations support the theoretical description of

these events, put forward by Cowley *et al.* [1991] and Smith *et al.* [1992]. This is based on the concepts of flow excitation and decay developed by Cowley and Lockwood [1992]. The occurrence of reconnection bursts causes periodic motions of the merging gap location, but strong (and zonal) flow bursts only if the IMF B_y component is large in magnitude. Periodic reconnection events, with the same spacing as magnetopause FTEs, could give rise to almost steady poleward flows, and these would be the only flows were the IMF B_y small. These concepts were also used by Lockwood and Smith [1989] to explain cusp ion dispersion in terms of FTE signatures. The merging gap motions would be typically $1\text{--}3^\circ$, which is well within the scatter of the observed latitude of the equatorward boundary of the cusp, as presented in the statistical survey by Newell *et al.* [1989].

The third conclusion relates to the significance of the altitude of the 630-nm emission. For the above description the importance of these transient events to the overall ionospheric and magnetospheric convection (as quantified by the transpolar voltage), is in simple proportion to both their area and their repetition frequency. For the given angular extent seen from the ground, the area that the transient 630-nm luminosity covers is proportional to the square of the emission altitude. Past work and interpretation has adopted a nominal altitude of 250 km for the 630-nm emission. We present here an argument that some 630-nm transient events occur at twice this height. We also show here that of the two events considered here one indeed arose from at least 400 km, and possibly 500 km or higher. We conclude that these transient events thus may be significantly more important to polar convection than previously suggested and that determination of the 630-nm emission altitude is vital for quantifying their role. We also note that for most events, the full longitudinal extent is not well known, because of the low camera sensitivity at large zenith angles. Observations from a longitudinal chain of such cameras may call for a further upward revision of the contribution of these events to convection. At times, transient reconnection events could therefore be the primary driving mechanism for convection.

Last, we note that the westward moving event studied here was consistent with the 630-nm emission from 250 km altitude and gave considerable 557.7-nm emission. Conversely, the eastward moving event was consistent with a 630-nm emission altitude of nearer 500 km and was associated with a relatively weak and short-lived 557.7-nm transient. Specifically, the 557.7-nm transient collocated with the upward transient current in the westward moving event was much stronger, and some 557.7-nm emission was detected within the 630-nm transient. The higher value of the $I(557.7 \text{ nm})/I(630 \text{ nm})$ intensity ratio inside the event indicates that the precipitating electron spectrum is somewhat harder for the January 12, 1988, event. It is not clear from this study whether this difference is related to the sense of motion of the two events (and hence the IMF B_y polarity), or to other factors. One possibility is that the Alfvén speed at the magnetopause was different for these two events. This determines the speed with which newly opened field lines move along the magnetopause and hence the acceleration of magnetopause ions which enter along the field lines. It is possible that the subsequent ion time-of-flight characteristics influence the electron precipitation by the weak ambipolar electric fields which maintain the observed quasi-neutrality

in the cusp region. Such ideas call for considerable further study, both experimental and theoretical. However, it does appear that relatively few eastward moving transient events have been observed using the 557.7-nm ISIT camera [Sandholt, 1988], whereas they are readily observed using the 630-nm CCD camera [Lockwood et al., 1990c; Sandholt et al., 1990a; Sandholt et al., 1992a]. This suggests that the differences in the intensity of the main 557.7-nm transient on the edge of the 630-nm transient (as opposed to those in the low-level 557.7-nm emission within the 630-nm transient) may indeed be related to an asymmetry with respect to the IMF B_y component. The reasons for any such asymmetry are not known. We note that the region of the upward field-aligned current (where the main 557.7-nm transient is observed) maps magnetically to the subsolar LLBL for IMF $B_y < 0$ (for northern hemisphere events) whereas it maps to the mantle region for $B_y > 0$. This may give a different source population for electron current carriers. We also note that the current contribution of upwelling ionospheric ions in the cleft ion fountain may introduce an asymmetry between these two cases.
